### The Markotwiz's model

- Reward and risk (measured by variance) are the two criteria that should be considered in defining efficient portfolios
- For a given level of expected return, determine the portfolio with minimum variance
- For a given level of risk, determine the portfolio with maximum expected return
- H. Markowitz 1990 Nobel Memorial Prize in Economic Sciences

Antonio VIOLI

- Let N denote the universe of assets
- For each asset  $i = \ldots, N$  let
  - $\overline{r}_i$  the expected rate of return of asset *i*
  - $\sigma_{ij}$  the covariance of the return of asset *i* and *j*
- ► We denote by x<sub>i</sub> the decision variable associated with the percentage of money invested in asset i
- We assume that the decision variables are non negative (no short selling are allowed)

- $\blacktriangleright$  Let  $\gamma$  be a threshold on the expected portfolio return
- The Markowitz's model is as follows

$$\min z = \sum_{i=1}^{N} \sum_{j=1}^{N} \sigma_{ij} x_i x_j$$
$$\sum_{i=1}^{N} \overline{r}_i x_i \ge \gamma$$
$$\sum_{i=1}^{N} x_i = 1$$
$$x_i \ge 0 \qquad i = 1, \dots, N$$

□ ▶ 《 臣 ▶ 《 臣 ▶

- The Markowitz's model belongs to the class of nonlinear (quadratic) programming problem
- ▶ By solving several instances of the Markowitz's model associated with different  $\gamma$  values we obtain different points in the  $(\bar{r} \sigma)$  plane
- By taking the convex combinations of these points, we get the efficient frontier

We denote by

- $\bar{\mathbf{r}}$  the vector of expected returns
- e the vector of 1
- x the vector of decision variables
- V the variance-covariance matrix

$$\min z = \mathbf{x}^T V \mathbf{x} \\ \mathbf{\bar{r}}^T \mathbf{x} \ge \gamma \\ \mathbf{e}^T \mathbf{x} = 1 \\ \mathbf{x} \ge \mathbf{0}$$

- Rather than considering different γ values, the efficient frontier can be determined by adopting a bi-objective approach
- Let  $\lambda$  denote a given scalar taking values in the interval [0,1]
- The mean-variance formulation is as follows

$$\begin{split} \min z &= \lambda * (\mathbf{x}^T V \mathbf{x}) - (1 - \lambda) * (\mathbf{\bar{r}}^T \mathbf{x}) \\ \mathbf{e}^T \mathbf{x} &= 1 \\ \mathbf{x} \geq \mathbf{0} \end{split}$$

- The parameter  $\lambda$  measures the risk aversion attitude
  - $\blacktriangleright$   $\lambda$  values close to 1 are used to model a high risk aversion level
  - $\blacktriangleright$   $\lambda$  values close to 0 denote a risk neutrality position

# The efficient frontier

#### The optimal allocation

• The higher  $\lambda$ , the more diversified the portfolio

<->→ □→ < □→</>

< ≣ >

The basic Markowitz model presents several limitations(drawback)

- Data estimation
- Lack of real features
- Inadequacy of variance as risk measure
- Single-period perspective

- ► The information required by the Markowitz model grows substantially as the number *N* of assets incresaes
- For example, for a portfolio of small size (N = 50), it is necessary to calculate:
  - 1. N = 50 estimates of expected returns

2. 
$$N = 50$$
 estimates of the variance

$$\frac{N*(N-1)}{2} = 1255$$

estimates of covariance

1325 total estimates

- The randomness displayed by the returns of N assets often can be traced back to a smaller number of underlying basic sources of randomness (termed factor)
- ► For common stocks, the main factor is a proper market index
- If we denote by  $\tilde{r}_m$  the random variable associated with the index return, then we assume that

$$\widetilde{r}_i = f(\widetilde{r}_m)$$

We assume that the rates of return and the factor are related by the following equation:

$$\widetilde{r}_i = \alpha_i + \beta_i * \widetilde{r}_m + e_i$$

- $\alpha_i$  and  $\beta_i$  are fixed constants
- e<sub>i</sub> are random quantities which represent errors

We shall assume that

The errors have zero mean

$$\mathbb{E}[e_i] = 0$$

The errors are uncorrelated with the market index

$$\mathbb{E}[e_i(\widetilde{r}_m-\overline{r}_m)]=0$$

The errors are uncorrelated

$$\mathbb{E}[e_i e_j] = 0 \quad j \neq i$$

The parameters for the mean-variance analysis are

$$\overline{r}_i = \alpha_i + \beta_i \overline{r}_m$$

$$\sigma_i^2 = \beta_i^2 \sigma_m^2 + \sigma_{e_i}^2$$

$$\sigma_{ij} = \beta_i \beta_j \sigma_m^2$$

□ ▶ 《 臣 ▶ 《 臣 ▶

These equations reveal the primary advantage of a factor model

- For a portfolio of small size (N = 50) we have to calculate:
  - 1 estimate of the expected rate of the market index return
  - 1 estimate of the variance of the return of the market index
  - ▶ 50 estimates of the  $\alpha$ ,  $\beta$  and the variance of the errors
- 152 total estimates
- ► In general for *N* assets

3*N* + 2

#### Parameter estimation

- The values of β<sub>i</sub> are estimated using the method of least squares
- ▶ Given a set of observations, represented as points in the plane (r<sub>i</sub>, r<sub>m</sub>), we look for the "best" straight line that interpolates them
- "Better" in the sense of minimizing the mean square error between the observed data and the estimated

#### Parameter estimation

• Let us denote by M the number of historical observations  $(r_{ik}, r_{mk})$  with k = 1, ..., M

$$e_{ik} = r_{ik} - \alpha_i - \beta_i r_{mk}$$

• We look for the  $\alpha_i$  and  $\beta_i$  values that minimize

$$\frac{1}{M}\sum_{k=1}^{M}e_{ik}^{2}$$

By solving

$$\beta_i = \frac{\sigma_{im}}{\sigma_m^2}$$
$$\alpha_i = \overline{r}_i - \beta_i \overline{r}_m$$

Portfolio variance

$$\sigma_{p}^{2} = \sum_{i=1}^{N} x_{i}^{2} \beta_{i}^{2} \sigma_{m}^{2} + \sum_{i=1}^{N} x_{i}^{2} \sigma_{e_{i}}^{2} + \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{j\neq i}^{N} x_{i} x_{j} \beta_{i} \beta_{j} \sigma_{m}^{2}$$

Expected return of portfolio

$$\sum_{i=1}^{N} x_i \alpha_i + \sum_{i=1}^{N} x_i \beta_i \overline{r}_m \ge \gamma$$

白 ト イヨト イヨト

- A general problem with the mean-variance model for risk-averse investors is that the optimal portfolios often contain a large number of individual stocks, making them very expensive to purchase and to manage
- A natural question is how to limit the number of stocks in the portfolio
- There are at least two obvious ways to do so
  - Simply limit the number of stocks present in the portfolio.
  - Explicitly modeling transactions costs subtracting them out of the expected returns

## **Diversification limits**

- Let y<sub>i</sub> denote a binary variables taking the value 1 if asset i is included on the portfolio and 0 otherwise
- ▶ We assume that here are lower *l<sub>i</sub>* and upper *u<sub>i</sub>* limitations on the fraction of capital invested capital in each asset

$$x_i \leq u_i y_i$$

$$x_i \geq l_i y_i$$

We may want to impose that the number of assets in our portfolio is at most K

$$\sum_{i=1}^{N} y_i \leq K$$

- Typically financial institutions may charge a fixed fee each time they execute a transaction involving a particular type of security.
- Such a fee may have a limiting effect on the number of different securities in the optimal portfolio, and is significant enough in most real-world applications to be considered as a necessary part of the model.
- To model transaction cost we introduce a binary variable y<sub>i</sub> taking the value 1 if asset i is included on the portfolio and 0 otherwise

 Transaction cost determine a reduction of the portfolio expected return

$$\sum_{i=1}^{N} \overline{r}_i x_i - \sum_{i=1}^{N} f * y_i$$

Note that variables x<sub>i</sub> should be related to the y<sub>i</sub>

 $x_i \leq u_i y_i$ 

 $x_i \geq l_i y_i$ 

 $l_i$  and  $u_i$  may be eventually set to 0 and 1, respectively

# Remarks

- ► A further problem with the traditional Markowitz model is the return distribution assumption on which it is implicitly based
- In the model, only the first two moments of the distribution, i.e. the expected value and the variance, are considered while higher moments such as skewness and kurtosis are ignored.
- Traditional risk/return optimization therefore assumes that returns follow a normal distribution.
- Empirical studies demonstrate, however, that normal distribution, especially during periods of market turbulence, significantly underestimates the likelihood of strongly negative returns.
- Empirical return distributions are not symmetric and exhibit fat tails.
- One way of resolving the problem is to incorporate forward-looking performance scenarios

The scenario-based approach poses a number of important issues

- How realistic scenarios could be generated ? As we shall see in the course, we can adopt simulation techniques
- Once generated, how scenarios can be included in the mathematical models?

We have to introduce some sophisticated modeling paradigms

The scenario-based approach will allow us to elaborate on different risk measures, overcoming the intrinsic limitations of the variance
